This document contains four appendices to Stanczyk et al. (2021).

**Appendix A.** *Details on the Technical Approach* gives additional detail on the methods used to obtain the findings presented in the report. This section includes information about how we conducted the literature scan, calculated the effect sizes from the original studies, conducted meta-analysis, and developed meta-regression models.

**Appendix B.** *Additional Table and Figures* provides the full results for each analysis presented in the report.

**Appendix C.** *Sensitivity Analysis* presents and describes checks of the sensitivity of key findings presented in the report to key analytic decisions.

**Appendix D.** *Citations Included in the Pathways Clearinghouse* lists the citations for the studies included in the meta-analysis data set.

Appendix A: Details on the Technical Approach

### A. Literature scan

The goal of the literature scan was to conduct a targeted review of past research that provided insights into how or why effects of interventions aimed at improving employment outcomes among people with low incomes might differ depending on the economic context.

To conduct the scan, we built off a recent, related review by the Clearinghouse for Labor and Evaluation Research (Clearinghouse for Labor Evaluation and Research 2020). First, we included all relevant articles from this review. Next, we conducted a Google Scholar search for additional relevant peer-reviewed articles, government reports, and working papers. We conducted the search using a set list of terms to capture phrases related to economic conditions, types of interventions, and focal populations of interest for this report (Table A.1). We screened search results for relevance and extracted relevant information from each screened-in resource into a matrix.

Topics	Search terms
Economic conditions	recession OR "economic recovery" OR "economic expansion" OR "business cycle"
Intervention	"Active labor market" OR "training" OR apprenticeships OR "career pathways" OR "employment coaching" OR "employment retention services" OR "job search assistance" OR "subsidized employment" OR "transitional jobs" OR "work experience" OR "work readiness activities" OR internships
Population	"low-income" OR "less-skilled" OR "low-skill"

#### Table A.1. Literature scan search terms

Our search resulted in more than 20,000 results. Given the targeted nature of this literature scan, we relied on the Google Search algorithm to guide our screening and examined the 800 search results tagged as most relevant. We more closely screened 20 search results for possible inclusion. Of these, we extracted data from 13 articles into a review matrix—and ultimately included findings or insights from 6 articles in the report.

One Pathways Clearinghouse staff member conducted the search, screened search results for relevance, and completed the review matrix. A second staff member reviewed all results. We looked across matrix entries for each study examined to identify cross-cutting themes.

### B. Meta-analysis and meta-regressions

This section provides further technical details on the meta-analysis and meta-regression methods used by the Pathways Clearinghouse to combine and contrast findings across studies and interventions. Meta-analysis and meta-regression enable us to combine the findings catalogued by the Pathways Clearinghouse into meaningful conclusions about what works, for whom, and in what context (Higgins and Green 2011). Meta-analysis produces an average estimate of impacts, with more weight given to more precise estimates. This averaging is valuable because each impact estimate might have flaws. As a rule, some studies will overestimate effects, and others will underestimate effects. Because of this, averaging findings across studies produces a more reliable estimate of the effect than that of any individual study.

Meta-regression further enables us to investigate different dimensions simultaneously. Metaregression builds on standard regression models in which an outcome variable (for example, earnings) is examined in relationship to one or more explanatory variables (for example, demographic characteristics). But there are some differences between regression and metaregression. A meta-regression analyzes outcomes from different studies rather than outcomes from different people. The outcome variable is the effect size in meta-regression, whereas the explanatory variables are characteristics of studies that might influence the size of that effect. Also, the data is weighted so larger studies have more influence on the estimated relationships than smaller studies.

#### 1. Calculation of effect sizes and their variances

When possible, the Pathways to Work Evidence Clearinghouse team calculated effect sizes as Hedges' g, the ratio between the estimated impact of the intervention and the standard deviation pooled across intervention and comparison groups. In particular, we calculated Hedges' g as:

$$g = \frac{\omega(y_i - y_c)}{S}$$

where  $y_i$  and  $y_c$  are the means of the outcome for the intervention and comparison groups,  $\omega$  is an adjustment for sample size (Hedges 1982, Hedges and Olkin 1985), and S is the pooled standard deviation of the outcome.  $\omega$  and S may further be calculated as

$$\omega = 1 - \frac{3}{4(n_i + n_c) - 9}$$
$$S = \sqrt{\frac{(n_i - 1)s_i^2 + (n_c - 1)s_c^2}{n_i + n_c - 2}}$$

where  $n_i$  and  $n_c$  are the number of people in the intervention and comparison groups, and  $s_i^2$  and  $s_c^2$  are the variances of the outcome for the intervention and comparison groups. Furthermore, we defined the variance of an effect size, g, as:

$$\sigma^2 = \frac{1}{n_i} + \frac{1}{n_c} + \frac{g^2}{2(n_i + n_c)}$$

Hedges' g is one of the most widely used effect size estimates, but some systematic reviews and meta-analyses use alternative indices to estimate effect sizes for binary variables (that is, those that take on values of 0 and 1 only, such as employment). For example, the What Works Clearinghouse uses the Cox index. Although research has shown that using the Cox index can be preferable to using Hedges' g, this research is based on assumptions that are unlikely to hold for the key binary outcomes of interest to the Clearinghouse (Sánchez-Meca et al. 2003). For

example, the Cox index produces artificially large effect sizes when most people in the sample have a 0 or 1 value for the outcome of interest, a condition that holds for employment and benefit receipt in some studies the Pathways Clearinghouse has reviewed. This analysis therefore used Hedges' g for both binary and nonbinary variables.

Researchers have developed a wide variety of alternative formulas for computing g (for example, see Lipsey and Wilson 2001), and the actual calculation of an effect size from a study depends on the type of statistics reported (for example, t-statistics, F-tests, or regression coefficients). Rotz et al. (2020) provides further details on the formulas used by the Pathways Clearinghouse based on the data reported.

To ensure the meta-analysis results were consistent and interpretable, we coded all effect sizes such that positive values indicated a favorable treatment effect. In particular, because the Pathways Clearinghouse aims to explore studies that help people become more economically self-sufficient, decreases in public benefit receipt were viewed as favorable outcomes. Therefore, we transformed decreases in public benefit receipt into positive effect sizes (and increases into negative effect sizes). We made this change for 779 public benefit receipt effect sizes (including measures of short-term benefits not included in this meta-analysis).

In addition, we used an alternative measure of the effect size,  $ES_{alt}$ , when study authors did not provide sufficient information for us to estimate Hedges' g. To calculate  $ES_{alt}$ , we used (1) the study's measure of an intervention's impact and (2) a nationally representative measure of the standard deviation of the outcome, based on the Integrated Public Use Microdata Series version of the Current Population Survey (CPS) (Flood et al. 2018). The CPS is a nationally representative survey of U.S. households that has consistently collected information on income and employment since 1962. We used the CPS to calculate one standard deviation for each outcome in each year from 1990 to 2019. In other words, we used the same S to construct effect sizes for the same outcome in different studies.

To estimate the appropriate standard deviations using national data, we first identified the people in the CPS who could reasonably be considered to have low income. Ideally, this would include people with low earnings potential and not those who have low earnings as the result of temporary investments in education or unemployment (for example, a graduate student pursuing an advanced degree, or a highly skilled individual who was recently laid off). To identify people with lower earnings potential, we first ran a regression analysis using education, age, gender, and race and ethnicity to predict income within each CPS survey year from 1990 to 2019 (including only people ages 16 to 65). We then defined people as having low income if their predicted income was in the bottom 20 percent of the distribution of predictions. We selected this threshold because about 20 percent of adults in the United States participate in government assistance programs in any given month (Irving and Loveless 2015). Finally, we used the actual outcome values for this population to estimate outcome standard deviations. We used the CPS to calculate standard deviations for several key outcomes (see Rotz et al. 2020 for further details):<sup>1</sup>

- Annual earnings (CPS wage and salary income)
- Monthly earnings (CPS wage and salary income)
- Quarterly earnings (CPS wage and salary income)
- Annual cash-based public assistance income
- Monthly cash-based public assistance income
- Number of months received cash-based public assistance in past year
- Annual value of food stamps or Supplemental Nutrition Assistance Program (SNAP) benefits
- Monthly value of food stamps or SNAP benefits (only available from 1995 to 2014)
- Number of months received food stamps or SNAP benefits in past year
- Hourly wage rates
- Weekly earnings in current job

Hedges' g and ES<sub>*alt*</sub> answer slightly different research questions by comparing impact estimates against the variation of the outcome in different samples. Using study data to calculate effect sizes produced estimates of the size of an intervention's effects relative to variation in the outcome for study participants (Hedges' g). Using national data to calculate effect sizes produced estimates of the size of effects relative to variation in the outcome across the U.S. low-income population (ES<sub>*alt*</sub>). We used Hedges' g in our analysis whenever it was available. The two measures of the standard deviation produce similar average effect sizes (Streke and Rotz 2021).

#### 2. Sample selection

To create the analytic sample for this report, we began with all effect sizes, studies, and interventions generated by the first two waves of the Pathways Clearinghouse reviews. We then applied the following restrictions:

- Keep only high- and moderate-rated studies and outcomes. We only included findings that Pathways Clearinghouse reviewers gave a high or moderate study quality by finding rating. These findings were generated using methods that support the conclusion that the intervention itself—rather than an outside, confounding factor—caused the observed change in outcomes.
- **Drop findings in the short-term public benefits domain.** Because increased use of public benefits during recessions is expected and often part of program design, we did not include findings for short-term public benefit receipt in this report.

<sup>&</sup>lt;sup>1</sup> All listed outcomes are continuous. Standard deviations for binary outcomes can be calculated based on the means of these variables, making the use of nationally representative data unnecessary.

- **Drop findings where the effect size is missing.** 203 findings were missing the information (typically, the standard deviation of the outcome) needed to calculate an effect size and were dropped.
- **Drop findings missing information on timing of enrollment.** This report used information recorded by Pathways Clearinghouse reviewers on the timing of participant enrollment to classify studies by economic conditions. One remaining finding was missing information on enrollment timing—because this information was not available in the study manuscripts—and was dropped.

Following these sample restrictions, the remaining analytic sample for this report included 1,423 effect sizes, drawn from 188 studies of 141 interventions.

### C. Statistical analyses

#### 1. Fixed effect and random effect models

The two most common types of models that exist for meta-analysis are fixed effects and random effects models. A fixed effects model assumes that all studies are estimating the same (fixed) treatment effect, whereas a random effects model allows for differences in the treatment effect from study to study. That is, fixed effects models assume that the only reason effect sizes differ is because of random chance and that, in the absence of this random chance, all studies would estimate the same impact. In contrast, random effects models assume that effect sizes might differ for other reasons, such as differences in the effect sizes being combined in a meta-analysis are equal to zero, whereas random effects models test whether the average of the effect sizes being combined is equal to zero (Borenstein et al. 2009). In general, random effects models are seen as more conservative than fixed effects model because they result in wider confidence intervals (Borenstein et al. 2009).

Whenever possible, we used random effects models for our analysis. The studies included in the Pathways Clearinghouse estimate effects for a range of interventions, making it likely that effect sizes differ for reasons other than random chance. As such, a random effects model was most appropriate (Borenstein et al. 2009).

However, for meta-analyses including a small number of studies, we needed to use a fixed effects model. Random effects models estimated with robust variance estimates (as described later) can produce unreliable estimates with a small number of included studies, in particular, when there are fewer than 10 studies contributing to the model (Tanner-Smith and Tipton 2012). The fixed effects model, while having less desirable assumptions, enabled us to avoid this concern. In practice, we used fixed effects models to estimate average effects by intervention but random effects models otherwise. For the intervention average effects, we therefore implicitly assumed that different implementations of the same intervention would have the same effect.

#### 2. Analysis weights

In estimating fixed effect and random effects models, we averaged effect sizes within and across studies. We weighted the individual effect sizes being aggregated to account for the fact that some estimates are more precise than others (Hedges and Olkin 1985).

For fixed effects analyses, we used weights equal to the inverse of an effect size's variance:

$$w_{i,fe} = \frac{1}{\sigma_i^2}.$$

The random effects model weights each study by the inverse of the variance plus a constant ( $\tau^2$ ) that represents the variability across the population effects, as well as adjusting for the number of effect sizes contributed to the analysis by a study ( $k_i$ ) and the correlation in those effect sizes ( $\rho$ ):

$$w_{i,re} = \frac{1}{\{(\sigma_i^2 + \tau^2)[(1 + (k_i - 1)\rho]\}}$$

That is, the random effects weight also incorporates information about how much the effect sizes vary from one another via tau-squared ( $\tau^2$ ). Substantively, a small tau-squared estimate indicates that evidence is consistent across effects. It is conservatively assumed that the correlation ( $\rho$ ) is equal to 1 in the random effects weight calculations (Tanner-Smith and Tipton 2012).

#### 3. Handling within-study dependence of effect sizes

Our analysis accounts for the fact that effect sizes from the same study are not independent measures of intervention effectiveness. Because many studies reported multiple effect sizes for the same participant samples (for example, short-term and long-term measures of employment measures), we found that it was not feasible to assume independence of the effect size estimates. Failing to account for this dependency could result in incorrect measures of estimates' precision.

The best approach to correct for within-study dependence of effect sizes is to account for the actual relationships between effect sizes from the same study when estimating the standard errors of the parameters. But, in practice, the information needed to do this is not readily available.

We used two approaches to account for the statistical dependencies in our analysis: robust variance estimation techniques and the "synthetic effect size" approach.

• **Robust variance estimation (RVE) for random effects models.** RVE uses estimation techniques that account for the statistical dependencies among effect sizes in the same study, as outlined by Hedges and others (Hedges et al. 2010; Tanner-Smith and Tipton 2012). In particular, Hedges et al. (2010) demonstrate that one can use regression results to infer the extent of the within-study dependence of effect sizes and adjust regression results accordingly. Simulation results show that when estimating the average effect size, 10 studies

is sufficient for RVE to provide reasonable standard error. We implemented RVE using the STATA robumeta package (Hedberg et al. 2017).

• Synthetic effect sizes for fixed effects models. In this approach described by Lipsey and Wilson (2001), we estimated the average effect size for each study (weighing by w<sub>i,fe</sub>) and performed meta-analysis on these study averages.<sup>2</sup> By including only one effect size for each study, we can assume each effect size is independent from those for the other studies included in the analysis. We implemented this approach using the Stata meta package.

#### 4. Regression model

Meta-regression allows a researcher to simultaneous investigate the effects of several characteristics on effect sizes. Our meta-regression models included the following characteristics:

- Type of primary service (some models)
- Study characteristics
  - Sample size
  - Whether an outcome was measured using survey or administrative data
  - Whether outcomes were compared to another intervention or business-as-usual
- Intervention and contextual characteristics
  - Duration
  - Whether the intervention was delivered by a public provider (as compared with a private provider or both public and private)
  - Whether the intervention was delivered in an urban context (as compared with rural or a combination of rural, urban, and suburban)
- Study sample characteristics
  - Share of participants identifying as female
  - Share of participants identifying as Black, Hispanic, White and not Hispanic, or of another racial and ethnic background
  - Whether all study participants were eligible for or receiving cash assistance
- Outcome characteristics
  - Type of measure (employment, earnings, or public benefits)
  - Timing of measure (short-term as compared with long- or very long-term)

<sup>2</sup>The variance of the study-level average effect size is estimated as  $\sigma_s^2 = \frac{1}{n_i} + \frac{1}{n_c} + \frac{g^2}{2(n_i + n_c)}$ , where  $n_i$  and  $n_c$  are the average sample sizes for the individual effect sizes used to create the study-level average. When combining study average effect sizes across studies, we weighted the average effect sizes by  $1/\sigma_s^2$ 

#### 5. Missing data

The analysis sample is limited to findings with nonmissing effect sizes. All findings also include data on the primary and other services provided as part of the intervention. But information on some characteristics was missing for some findings. For almost all characteristics examined, less than 10 percent of data were missing. But two characteristics had 17 to 19 percent of data missing: intervention duration and the percent of the study sample that was female.

For meta-regressions examining multiple characteristics at once, we replaced missing values with a characteristics' mean value. For the two characteristics that were missing for more than 10 percent of observations, we also included in the regression model an indicator variable equal to one if the value was imputed and zero otherwise (a total of two indicators were included). Methods for missing data have not been studied extensively in the context of meta-analysis (Pigott and Polanin 2020) but mean imputation is a widely used and commonly accepted tactic for handling missing data in other contexts (Rotz et al. 2020).

Source: Pathways Clearinghouse database.

Note: Tau-squared  $(\tau^2)$  indicates the extent of variation among the effects observed in different studies. For some studies, the enrollment period included both recession and recovery years. In these cases, we include the given study in analyses focused on studies for which enrollment occurred during a recession and in analyses focused on studies for which enrollment occurred during a recovery. Analyses focused on studies for which enrollment only include studies for which all years in the enrollment period were classified as stable.

p < .10. \*\* p < .05. \*\*\* p < .01.

CI = confidence interval.

Source: Pathways Clearinghouse database.

Note: Mixed-effects meta-regression models were estimated with robust standard errors to account for dependent effect sizes estimates. Number of effect sizes = 1,438. Number of studies = 188. For some studies, the enrollment period included both recession and recovery years. In these cases, we categorized the study as occurring during a recession and as occurring during a recovery. Studies are classified as occurring during a stable economic period only if all years in the enrollment period were classified as stable. The model contains indicators for characteristics for which more than 10 percent of values were missing and mean-imputed. See Appendix A for additional details on missing data.

p < .10. \*\* p < .05. \*\*\* p < .01.

B = unstandardized regression coefficient; SE = standard error.

Note: Mixed-effects meta-regression models were estimated with robust standard errors to account for dependent effect sizes estimates. Number of effect sizes = 1,438. Number of studies = 188. For some studies, the enrollment period included both recession and recovery years. In these cases, we categorized the study as occurring during a recession and as occurring during a recovery. Studies are classified as occurring during a stable economic period only if all years in the enrollment period were classified as stable. The model contains indicators for characteristics for which more than 10 percent of values were missing and mean-imputed. See Appendix A for additional details on missing data.

p < .10. \*\* p < .05. \*\*\* p < .01.

B = unstandardized regression coefficient; SE = standard error.

Appendix C: Sensitivity Analysis

We tested the sensitivity of study results to key analytic decisions. In these sensitivity analyses, we focused on results considering economic conditions during enrollment, because these results were the primary focus of the report.

## A. Sensitivity to the selection of the within-study correlation between effect sizes

When using robust variance estimation for random effects models, it is standard to test sensitivity to the selection of the within-study correlation between effect sizes, or  $\rho$  (Tanner-Smith and Tipton 2012). Following the literature, we used 0.8 as the value for  $\rho$  in main analyses, and we re-estimated results using the following values for  $\rho$ , in turn: 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, and 0.9. Results were unchanged. We did not present results of this sensitivity test here, for brevity, but results are available by request.

### B. Sensitivity of results to unemployment cutoffs used to assign each year to an economic period

In the main analysis, we used a 0.5 percentage point cutoff for annual change in the unemployment rate to assign each year to an economic period. For these sensitivity analyses, we used two alternate cutoffs—one that uses 50 percent of the main version or a 0.25 percentage point cutoff (Table C.1 and C.2), and one that uses 200 percent of the main cutoff or a 1 percentage point cutoff (Table C.3 and C.4). In general, the pattern of results described in the main text was robust to the chosen cutoff.

# C. Sensitivity to using National Bureau of Economic Research (NBER) business-cycle dates rather than changes in unemployment rates to assign each year to an economic period

In the main analysis, we used annual changes in the unemployment rate to assign each year to an economic period (recession, recovery, or stable). Years classified following this method generally gave similar start and end dates of economic recessions published by NBER, a respected source for this information.<sup>3</sup>

In this sensitivity check, we re-estimated results using business-cycle dates published by NBER—rather than changes in unemployment—to classify years by economic condition. NBER provides dates for the peak and trough of each business cycle.<sup>4</sup> Using these dates, we defined recession years as those between the peak and the trough, recovery years as the first half of the years between each trough and the following peak—rounding down when there was an odd number of years between peak and trough—and stable years as the second half of the years between each trough and the following peak. We assigned each year to the economic conditions that existed in the majority of the year. For example, because a peak occurred in the first quarter of 2001 with the trough falling in the fourth quarter of 2001, we classified 2001 as a recession year. Similarly, because a peak occurred in the third quarter of 1990, we classified 1990 as a stable economic year and 1991 as a recession year.

This alternative classification scheme yielded more observations in recovery years (Table C.5 and C.6). But the pattern of results was similar to the main analyses. Where there were changes, they were primarily in the average effect sizes for stable economic periods. Given the focus of this report on labor market outcomes, we preferred the classification scheme based on changes in unemployment rates.

<sup>&</sup>lt;sup>3</sup> The National Bureau of Economic Research (NBER) defines only two types of economic periods: (1) economic recessions, or the period between the highest and lowest point of economic activity as determined by a committee of experts who consider a wide range of economic indicators, including employment and gross domestic product; and (2) economic expansions, or the period between the lowest and highest point. To enable us to examine the effectiveness of interventions and types of services during periods of economic recovery after a recession as compared with periods of more steady or regular economic activity, we considered three types of economic periods. We differentiated between recessions, recoveries from recessions, and what we called "stable economic periods" (neither recession nor recovery). Our definitions of these three periods are discussed in the text. <sup>4</sup> See https://www.nber.org/research/business-cycle-dating.

Table C.5. Average effects overall and by economic conditions during enrollment and when outcomes were measured, sensitivity check using NBER business-cycle dates to assign years to economic conditions

	Number of effect sizes	Number of studies	Average effect size	Standard error	95% CI	<i>p</i> -value	Tau- squared	
Overall	1438	188	0.050***	0.007	[0.037, 0.063]	<0.001	0.009	
Economic conditions when enrollment occurred								
Recession	313	34	0.034***	0.010	[0.014, 0.054]	0.002	0.007	
Recovery	1206	157	0.042***	0.007	[0.028, 0.056]	<0.001	0.008	
Stable	139	24	0.100***	0.020	[0.058, 0.142]	<0.001	0.010	
Economic conditions when outcomes were measured								
Recession	79	25	0.036***	0.012	[0.011, 0.061]	0.007	0.004	
Recovery	544	111	0.056***	0.008	[0.039, 0.073]	<0.001	0.009	
Stable	815	142	0.043***	0.007	[0.029, 0.057]	<0.001	0.007	

Source: Pathways Clearinghouse database.

Note: Tau-squared ( $\tau^2$ ) indicates the extent of variation among the effects observed in different studies. For some studies, enrollment period included both recession and recovery years. In these cases, we include the given study in analyses focused on studies for which enrollment occurred during a recession and in analyses focused on studies for which enrollment occurred during a recovery. Analyses focused on studies for which enrollment only include studies for which all years in the enrollment period were classified as stable.

p < .10. \*\* p < .05. \*\*\* p < .01.

CI = confidence interval; NBER = National Bureau of Economic Research.

Table C.6. Average effects by type of primary service and economic conditions during enrollment, sensitivity check using NBER business-cycle dates to assign years to economic conditions

	Number of effect sizes	Number of studies	Average effect size	Standard error	+95% Cl	<i>p</i> - value	Tau- squared
